## ABSTRACT

This study investigates hydrological responses to climatic shifts using sediment flux data derived from two dated palaeolake records in southeast (SE) Arabia. Flux values are generally low during the early Holocene humid period (EHHP) (~9.0 to 6.4 k cal a BP) although several short-lived pulses of increased detrital input are recorded, the most prominent of which is dated between ~8.3 and 7.9 k cal a BP. The EHHP is separated from the mid-Holocene humid period (MHHP) (~5.0 to 4.3 k cal a BP) by a phase of increased sediment flux and aridity, which began between ~6.4 and 5.9 k cal a BP and peaked between ~5.2 and 5.0 k cal a BP. The termination of the MHHP is marked by a phase of high detrital sediment flux between ~4.3 and 3.9 k cal a BP. Whilst long-term shifts in climate are most likely linked to changes in the summer position of the Intertropical Convergence Zone (ITCZ) and associated Indian and African monsoon systems, it is noted that the abrupt, short-term phases of aridity observed in both records are coeval with intervals of rapid climate change globally, which triggered non-linear, widespread landscape reconfigurations throughout SE Arabia.

## KEYWORDS

Arabia, sediment flux, Holocene, geochemistry, palaeolake

## INTRODUCTION

It has long been recognised that the world's low latitude regions were characterised by significant hydrological changes during the Late Glacial and Holocene in response to the shifting position of the Intertropical Convergence Zone (ITCZ) and associated monsoon rains (Sirocko *et al.*, 1993; deMenocal *et al.*, 2000; Fleitmann *et al.*, 2007; Tierney and deMenocal, 2013;

Shanahan *et al.*, 2015). Indeed, pioneering research by Alayne Street-Perrott documented widespread shifts in water balance from closed basin lakes in Africa, demonstrating major variations in rainfall and streamflow (Street and Grove, 1976, 1979). Her early work showed that the markedly arid conditions **that** characterised intertropical Africa during the Last Glacial Maximum (LGM) were followed by an early Holocene humid phase in which annual precipitation between 24°N and 8°S increased significantly. Further work suggested that these changes were driven by minimum precession and maximum insolation in the Northern Hemisphere (NH) (Kutzbach and Street-Perrott, 1985). The development of the Oxford Lake Level Data Bank (Street-Perrott *et al.*, 1989) **led to the compilation** of records of lake status, a measure of relative water depth (low, intermediate, high), for lake basins that would have been closed for part, or all, of their late Quaternary history. This work suggested that high NH summer insolation in the early to mid-Holocene enhanced the thermal contrast between land and sea, with the resultant strengthening of the summer monsoon systems leading to high lake levels and the re-adjustment of vegetation across both hemispheres (Street-Perrott and Harrison, 1984, 1985; Kutzbach and Street-Perrott, 1985). Furthermore, palaeoclimate records from central and northern Africa suggested that orbital forcing alone was insufficient to produce conditions wetter than today (Yu and Harrison, 1996) and that positive feedback drivers also contributed to enhanced rainfall. Street-Perrott and Perrott (1990, 1993) demonstrated that closed lakes in the tropics and subtropics amplify climatic signals and are thus excellent indicators of variations in water budget. They suggested that short-term variations, which tend to reflect regional hydrological perturbations that are superimposed on more long-term, orbital variability, were coincident with injections of fresh water into the North Atlantic.

1  
2  
3 70 The climate of the Arabian Peninsula is complex and results from the interaction of major  
4  
5  
6 71 atmospheric systems, namely the ITCZ and associated monsoon circulation, as well as mid-  
7  
8 72 latitude Westerlies (MLW). Consequently the region is a key area for understanding climate  
9  
10 73 change in low-latitude regions during the Late Glacial and Holocene. However, in comparison to  
11  
12 74 other low latitude deserts, such as the Sahel-Sahara, few independent, age-constrained, high-  
13  
14 75 resolution records are available from Arabia, and those there are have revealed significant  
15  
16 76 regional heterogeneity (sensu Thomas *et al.*, 2012) during the Holocene (Berger *et al.*, 2012).  
17  
18 77 Speleothem records from Oman provide a detailed insight into Holocene hydrological changes  
19  
20 78 caused by long-term shifts in the position of the summer ITCZ (Neff *et al.*, 2001; Fleitmann *et*  
21  
22 79 *al.*, 2007). However, coming from mountain locations relatively close to the ocean and marginal  
23  
24 80 to the peninsula as a whole, these records cannot readily be translated into evidence of wetter  
25  
26 81 landscape conditions in the interior. Also emerging is a well-dated record of multiple periods of  
27  
28 82 dune activity during the Holocene, derived from accumulation luminescence chronologies from  
29  
30 83 sediment cores in Oman (Preusser *et al.*, 2002), Liwa (Stokes and Bray 2005), and major dune-  
31  
32 84 sediment exposures throughout northern areas of the United Arab Emirates (UAE) (Atkinson *et*  
33  
34 85 *al.* 2011, 2012). Gaps in dune accumulation cannot be interpreted, without other evidence, to  
35  
36 86 represent wetter phases *per se* (Thomas and Burrough 2012, Leighton *et al.* 2014), and may be  
37  
38 87 controlled by sediment supply rather than climate (Preusser 2009). Thus while a better  
39  
40 88 framework of Arabian Holocene environments is emerging, the record, for the purposes of  
41  
42 89 addressing critical questions relating to landscape response, is either spatially limited (and  
43  
44 90 therefore at risk of over-extrapolation) or difficult to reconcile as a clear proxy of hydrological  
45  
46 91 change.

2  
3 93 This paper presents new data from two key sites of Holocene climate variability in southeast  
4  
5 94 (SE) Arabia; Awafi palaeolake and Wahalah palaeolake (Fig. 1). Previous work has determined  
6  
7  
8 95 that lacustrine conditions developed at both sites during the early to mid-Holocene, during which  
9  
10 96 a series of pronounced changes in lake hydrology, vegetation dynamics and landscape stability  
11  
12 97 are recorded (Parker *et al.*, 2004, 2006; Preston *et al.*, 2015). The site chronologies presented in  
13  
14 98 these studies were based on a relatively simple age-depth model (linear interpolation), the  
15  
16 99 drawbacks of which have been well documented (Telford *et al.*, 2004; Blaauw, 2010). Street-  
17  
18 100 Perrott *et al.* (2007) highlighted the importance of applying mass accumulation rates (MAR) and  
19  
20  
21 101 understanding changes in organic, siliclastic and biogenic mineral component flux rates to  
22  
23 102 sediment sequences as they overcome distortions resulting from variable sedimentation rates and  
24  
25 103 dilution effects (e.g. Barker *et al.*, 2001; Ficken *et al.*, 2002; Cockerton *et al.*, 2014). In this  
26  
27 104 paper, we present a strengthened chronological framework for both sites based on a Bayesian  
28  
29 105 age-depth model, which in turn allows the calculation of MAR and sediment flux data against  
30  
31  
32 106 which the existing palaeoclimate evidence from the region can be compared.

38  
39 108 **Environmental setting: climate and geomorphology**

40  
41 109 The study area is located in the northern United Arab Emirates (UAE), on the eastern margin of  
42  
43 110 the Arabian Peninsula (Fig. 1). The region presently experiences an arid to hyper-arid desert  
44  
45 111 climate, characterised by cool winters and hot summers. While highly variable, mean annual  
46  
47 112 precipitation (~120 mm/year) is somewhat higher compared to coastal areas further to the south  
48  
49 113 (e.g. ~80 mm/year in Dubai) (Parker *et al.*, 2006), highlighting the significant orographic effect  
50  
51 114 of the al-Hajar Mountains on precipitation gradients. Precipitation is highest during the winter  
52  
53  
54 115 months and is associated with MLW that originate in the Mediterranean and lead to increased  
55  
56  
57  
58  
59  
60

116 cyclogenesis throughout the eastern Mediterranean, the Red Sea and northern Arabia (Fisher and  
 117 Membery, 1998). The wind regime is dominated by the low-level *Shamal* winds, which peak  
 118 during the summer months as they blow from the northwest to southeast down the Arabian Gulf  
 119 before turning clockwise across the Rub' al-Khali (Glennie and Singhvi, 2002). The study region  
 120 is located to the north of the notional summer position of the ITCZ (Fig. 1), with monsoon-  
 121 sourced rainfall presently limited to southern margins of the Peninsula (e.g. Yemen Highlands).

123 The geomorphology of the northern UAE is highly varied and comprises a mixture of desert,  
 124 mountain, piedmont, and coastal environments (Parker and Goudie, 2008; Preston *et al.*, 2012).  
 125 The region is largely covered by Quaternary dune features belonging to the Rub' al-Khali sand  
 126 sea (560,000 km<sup>2</sup>), which extend into the area between the Arabian Gulf coastline (west) and the  
 127 al-Hajar Mountains (east) (Fig. 2). Provenance studies of the dune sands in the UAE have shown  
 128 that both are major sources of carbonate in the region, with the latter also contributing ultramafic  
 129 igneous material. Iron-rich quartz grains, derived from the Arabian continental interior, are a  
 130 third major component of the region's dune sands (El-Sayed, 1999; White *et al.*, 2001; Farrant *et*  
 131 *al.*, 2012). A vast bajada of alluvial fans has developed where upland drainage systems emanate  
 132 from the mountain front (Fig. 2).

134 Awafi palaeolake (25° 42' 57" N, 57° 55' 57" E; 6 m above sea level), initially revealed in the  
 135 1990s as a consequence of industrial quarrying, is a flat inter-dune depression (~2 km<sup>2</sup>). The  
 136 basin is bounded by northeast to southwest trending mega-linear ridges. There are no obvious  
 137 surface inlets or outlets and so the basin is considered to have been hydrologically closed, with  
 138 its main catchment area (ca. <5 km<sup>2</sup>) composed of the surrounding permeable dunes sands. The

1  
2  
3 139 current depth to groundwater in the region is estimated to be  $\leq 15$  m (Alsharhan *et al.*, 2001; p.  
4  
5 140 206). Sediment samples for this study were collected from an exposed sequence of over 2 m of  
6  
7  
8 141 stratified marls, silts and sands (Fig. 3), immediately adjacent ( $< 1$  m) to the original section  
9  
10 142 analysed by Parker *et al.* (2004, 2006).  
11  
12 143  
13  
14 144 Wahalah palaeolake ( $25^{\circ} 38' 48''$  N,  $55^{\circ} 47' 26''$  E; 10 m above sea level), located approximately  
15  
16 145 18 km to the southwest of Awafi, is also a dry, inter-dune depression ( $\sim 2.4$  km<sup>2</sup>). The basin is  
17  
18 146 considered to have been hydrologically closed with an overall catchment area of  $< 5$  km<sup>2</sup>, and is  
19  
20 147 bounded by mega-linear ridges. Similar to Awafi, there is no surface water at the site, with the  
21  
22 148 groundwater table estimated to be well below the present day surface ( $\leq 15$  m) (Alsharhan *et al.*,  
23  
24 149 2001; p. 206). Sediment samples for this study were collected from a 2 x 2 m trench dug into the  
25  
26 150 centre of the basin using a mechanical digger (Fig. 4).  
27  
28  
29  
30  
31  
32  
33

34 152 **Methods**

35  
36 153 Prior to sampling, the sediment sections at both sites were cleaned and logged using standard  
37  
38 154 sedimentological techniques. Contiguous 1 cm samples were then extracted for further laboratory  
39  
40 155 analysis to depths of 2.55 m and 2.14 m at Awafi and Wahalah respectively.  
41  
42  
43  
44  
45

46 157 Mass specific, low frequency magnetic susceptibility **(MS)** measurements were made using a  
47  
48 158 Bartington MS2 meter with an MS2B sensor at 0.1 SI unit sensitivity (Dearing, 1999). Dry bulk  
49  
50 159 density (DBD) (g cm<sup>-3</sup>) was measured as the dry weight of sediment per unit volume using the  
51  
52 160 method outlined in Parker (1995, pp. 67–68). Organic matter (OM) was calculated by loss-on-  
53  
54  
55 161 ignition (LOI) (Heiri *et al.*, 2001) and is reported as mass in mg cm<sup>-2</sup> a<sup>-1</sup>. Magnetic susceptibility,  
56  
57  
58  
59  
60

DBD and OM measurements were made on each sample. For particle size analysis, samples were taken at 5 cm intervals and treated with 30% hydrogen peroxide to remove organic matter before being soaked overnight in a solution of 5% sodium hexametaphosphate in de-ionised water. Grain size distributions between 0.02 and 2000  $\mu\text{m}$  were determined by laser diffraction spectrometry using a Malvern Mastersizer 2000. Major element concentrations were measured on bulk sediments using a Perkin Elmer Optima 3300RL ICP-AES, calibrated using single and multi-element standard solutions. Sample preparation followed the wet-chemical extraction procedure outlined in Engstrom and Wright (1984) and was undertaken at 2 cm intervals.

A combination of AMS  $^{14}\text{C}$  and OSL dating was used to constrain the chronologies of the sites and details are provided elsewhere (Parker *et al.*, 2006; Preston *et al.*, 2015) (Figs. 3 and 4). Calibration of radiocarbon dates was undertaken using the Intcal13 calibration curve (Reimer *et al.*, 2013). Age-depth modelling was performed on the  $^{14}\text{C}$  and OSL dates using the software package Bacon version 2.2 (Blaauw and Christen, 2011) with R version 3.1.2 (R Core Team, 2014) (Fig. 5). Bacon uses Bayesian statistics and Markov chain Monte Carlo (MCMC) methods to reconstruct sediment accumulation histories, and estimates sedimentation times ( $\text{a cm}^{-1}$ ) and ages through a dated section. Sedimentation times were converted into sedimentation rates (measured in  $\text{cm a}^{-1}$ ) by taking the reciprocal (i.e.  $1/\text{sedimentation time}$ ) (Fig. 6). The means of the MCMC-derived age-depth models and sedimentation rate estimates were used to calculate proxy flux rates (see below).

The mass accumulation rate (MAR) of sediment per sample at both sites was calculated following the method outlined in Street-Perrott *et al.* (2007) where MAR ( $\text{g cm}^{-2}\text{a}^{-1}$ ) equals DBD

1  
2  
3 185 ( $\text{g cm}^{-3}$ ) multiplied by the sedimentation rate (SR) ( $\text{cm a}^{-1}$ ), which is related to the respective  
4  
5  
6 186 depth-age relationship. The flux of magnetic minerals was calculated as follows:  $\text{FLUX} = \text{DBD}$   
7  
8 187  $\times \text{SR} \times \text{MS}$ . Geochemical flux values (Al, Fe, K, Si and Ti) are expressed as concentrations per  
9  
10 188 unit weight of sediment and expressed in ( $\text{mg cm}^{-2}\text{a}^{-1}$ ) and were calculated by multiplying the  
11  
12 189 MAR by the concentration by weight ( $\text{mg g}^{-1}$ ).  
13  
14  
15  
16

17  
18 191 The data generated by the above measurements are used to reconstruct changing environmental  
19  
20 192 conditions over time. Dry bulk density (DBD) is used to infer changing sediment properties, with  
21  
22 193 high values indicative of higher minerogenic content. Organic matter (OM) values are primarily  
23  
24 194 controlled by biological productivity, together with organic matter preservation (Meyers, 2003).  
25  
26 195 Magnetic susceptibility (MS) is used to infer stability in the surrounding dune-fields, with values  
27  
28 196 primarily controlled by the deposition of Fe-rich quartz during periods of dune remobilisation  
29  
30 197 (Preston *et al.*, 2012), and may in turn be linked to variations in vegetation cover, precipitation,  
31  
32 198 sediment supply and/or wind strength (Tsoar, 2005; Yizhaq *et al.*, 2009). Reduced sediment  
33  
34 199 input from the catchment is also inferred by lower Al, K, Fe, Si and Ti values, which correspond  
35  
36 200 to the abundance of quartz, feldspars and sheet silicates, all of which are common components of  
37  
38 201 the dune sands in the northern Emirates (El-Sayed, 1999; Farrant *et al.*, 2015). Low Na/Ti and  
39  
40 202 high Al/(Ca + Na) values are used to infer lake lowering, aridity and input of aeolian material  
41  
42 203 rich in Ti and Al.  
43

208

209 **Awafi**

210 The base of the Awafi sequence comprises homogeneous, fine sands (210 to 160  $\mu\text{m}$ ), with the  
 211 deposition of laminated marls with intermittent fine sands dated to  $\sim 8.3$  k cal a BP. Although  
 212 initially high, DBD ( $1.23 \text{ g cm}^{-3}$ ) and MAR ( $0.18 \text{ g cm}^{-2} \text{ a}^{-1}$ ) values steadily decline until  $\sim 8.2$  k  
 213 cal a BP after which a marked increase is observed in sediment mass accumulation rates (MAR)  
 214 (rising from  $0.08$  to  $0.28 \text{ g cm}^{-2} \text{ a}^{-1}$ ). A peak in detrital input occurs at  $\sim 8.1$  k cal a BP with  
 215 increases in the Al, Fe, K, Si and Ti. Two distinct peaks ( $>700$ ) are recorded in the Na/Ti data  
 216 between  $\sim 7.9$  and  $7.8$  k cal a BP before values fall abruptly. Detrital sediment input is low  
 217 between  $\sim 7.6$  and  $6.4$  k cal a BP and is associated with reduced sediment MAR, as well as low  
 218 geochemical flux values. Sediments comprise laminated marls with very fine sands and silts (105  
 219 to  $45 \mu\text{m}$ ). Organic matter (OM) flux values are very low ( $\sim 1 \text{ mg cm}^{-2} \text{ a}^{-1}$ ) between  $\sim 7.5$  and  $6.4$   
 220 k cal a BP.

221

222 Sediment MAR increases from  $\sim 6.4$  k cal a BP, corresponding with a steady increase in DBD  
 223 values between  $\sim 6.1$  ( $0.46 \text{ g cm}^{-3}$ ) and  $5.0$  k cal a BP ( $1.07 \text{ g cm}^{-3}$ ). The MS and geochemical  
 224 flux data all show increasing values from  $\sim 6.4$  k cal a BP, corresponding with an abrupt increase  
 225 in the sand component of the sediment. Organic matter (OM) flux shows increasing values  
 226 between  $\sim 6.4$  ( $0.68 \text{ mg cm}^{-2} \text{ a}^{-1}$ ) and  $\sim 5.5$  k cal a BP ( $8.02 \text{ mg cm}^{-2} \text{ a}^{-1}$ ), before steadily declining  
 227 to  $2.57 \text{ mg cm}^{-2} \text{ a}^{-1}$  at  $\sim 5.0$  k cal a BP. Magnetic susceptibility flux values increase slowly  
 228 between  $\sim 6.0$  and  $5.4$  k cal a BP, after which a steep increase is observed to  $\sim 5.0$  k cal a BP.  
 229 Na/Ti values fall rapidly at  $\sim 6.0$  k cal a BP from a peak of  $\sim 600$ . The period between  $\sim 5.0$  and  
 230  $4.3$  k cal a BP is characterised by decreasing MS flux values, reduced DBD and lower sediment

1  
2  
3 231 MAR. Sediments comprise very fine calcareous sands and silts (115 to 55  $\mu\text{m}$ ), with an overall  
4  
5 232 reduction in the sand component of the sediment. A distinct 10 cm band of very fine aeolian  
6  
7 233 sands (100  $\mu\text{m}$ ) is OSL dated to 4.10 ka. This layer corresponds with peaks in DBD, MS flux  
8  
9 234 ( $3.0 \times 10^{-5} \text{ cm a}^{-1}$ ), and the sand fraction ( $\sim 90\%$ ) although this is muted in the geochemical flux  
10  
11  
12 235 data.  
13  
14  
15 236

16  
17 237 **Wahalah**  
18

19  
20 238 The basal sediments at Wahalah are dated to  $\sim 9.4$  k cal a BP and comprise homogeneous, fine to  
21  
22 239 very fine sands (130 to 100  $\mu\text{m}$ ). At  $\sim 9.0$  k cal a BP, the aeolian sands are replaced by laminated  
23  
24 240 marls, with intermittent fine to very fine sands (220 to 100  $\mu\text{m}$ ). Sediment mass accumulation  
25  
26 241 rates (MAR) are low at the base of the sequence ( $\sim 0.05 \text{ g cm}^{-2} \text{ a}^{-1}$ ) before values increase abruptly  
27  
28 242 at  $\sim 8.4$  k cal a BP, peaking at  $0.13 \text{ g cm}^{-2} \text{ a}^{-1}$  between  $\sim 8.2$  and 8.0 k cal a BP. Magnetic  
29  
30 243 susceptibility (MS) flux values are low until  $\sim 8.2$  k cal a BP, when an increase to  $0.12 \times 10^{-5} \text{ cm}$   
31  
32 244  $\text{a}^{-1}$  is observed. Organic matter (OM) flux rates are initially low ( $0.42 \text{ mg cm}^{-2} \text{ a}^{-1}$ ) before rising  
33  
34 245 to  $1.42 \text{ mg cm}^{-2}$  between  $\sim 8.4$  and 7.9 k cal a BP. The curves for Al, Fe, K, Si and Ti all show  
35  
36 246 similar patterns with moderately high values between  $\sim 9.4$  and 9.0 k cal a BP, followed by a shift  
37  
38 247 to lower values between  $\sim 9.0$  and 8.3 k cal a BP. Distinct peaks are observed in the DBD and  
39  
40 248 geochemical flux data between  $\sim 8.2$  and 8.0 k cal a BP. An inverse trend is observed in the  
41  
42 249 Na/Ti data, with values falling from  $\sim 400$  at  $\sim 8.4$  k cal a BP to  $\sim 60$  at  $\sim 8.0$  k cal a BP. Between  
43  
44 250  $\sim 7.9$  and 6.0 k cal a BP, reduced flux rates are indicated by lower MAR, with sediments  
45  
46 251 comprising fine to very fine calcareous sands (170 to 90  $\mu\text{m}$ ). The sand component of the  
47  
48 252 sediment is lowest at this time although values steadily increase from  $\sim 7.4$  k cal a BP. Pulses of  
49  
50  
51 253 detrital sediment input are indicated by peaks in the MS, Al, Fe, K, Si, Ti flux data at  $\sim 7.6$ ,  $\sim 7.2$ ,  
52  
53  
54  
55  
56  
57  
58  
59  
60

254 ~6.8 and ~6.4 k cal a BP. Between ~7.8 and 7.6 k cal a BP Na/Ti values increase to ~370 before  
 255 falling abruptly.

256  
 257 Between ~5.9 and 5.2 k cal a BP there is a marked increase in DBD (from 0.78 to 1.03 g cm<sup>-3</sup>)  
 258 coinciding with the deposition medium to fine aeolian sands (280 to 120 µm). Magnetic  
 259 susceptibility flux values rise sharply from 0.09 to 0.31 x 10<sup>-5</sup> cm a<sup>-1</sup> at ~5.9 k cal a BP and  
 260 remain high until ~5.2 k cal a BP. A peak (>90%) is observed in the sand component of the  
 261 sediment at ~5.7 k cal a BP. Organic matter (OM) flux rates decline to ~0.27 mg cm<sup>-2</sup> a<sup>-1</sup> and  
 262 remain low throughout the rest of the sequence. Al, Fe, K, Si and Ti flux values all rise abruptly,  
 263 whilst Na/Ti values decline to ~30, the lowest of the sequence. After ~5.0 k cal a BP detrital  
 264 sediment input is reduced, as denoted by the decreases in the MS, Al, Fe, K, Si, Ti flux values  
 265 and the Al/(Ca+Na) data. Sediments comprise fine to very fine calcareous sands (190 to 120  
 266 µm). Between ~4.2 and 3.9 k cal a BP MS flux values increase from 0.07 to 0.31 x 10<sup>-5</sup> cm a<sup>-1</sup>  
 267 with values then falling to 0.18 x 10<sup>-5</sup> cm a<sup>-1</sup> at ~3.8 k cal a BP. Al, Fe, K, Si and Ti flux values  
 268 all increase at this time. Al/(Ca+Na) values increase from 0.11 to 0.45 between ~4.3 and 4.1 k  
 269 cal a BP.

270

## 271 **DISCUSSION**

272 The records derived from the Awafi and Wahalah sediment sequences are well documented  
 273 (Parker *et al.*, 2004, 2006; Parker and Goudie, 2008; Preston *et al.*, 2015) and have in turn raised  
 274 important palaeoclimatic questions. Evidence from both sites supports the notion that aridity  
 275 prevailed throughout SE Arabia during the LGM and earliest Holocene (Parker, 2010; Farrant *et*  
 276 *al.*, 2015), with a large number of OSL-dated dune records suggesting increased accumulation

60

and preservation between ~16 and 9 ka (Leighton *et al.*, 2014) (Fig. 9). At Awafi, 7 m of dune accumulation occurred between 13.5 and 9.1 ka ( $1.60 \text{ m ka}^{-1}$ ) (Goudie *et al.*, 2000) and at Wahalah two dune sequences yielded a net accumulation rate of 3 to 4 m  $\text{ka}^{-1}$  between 15.9 and 10.3 ka (Atkinson *et al.*, 2011; Leighton *et al.*, 2014). The accumulation of sands and the higher flux levels at the base of both sequences support the notion that the surrounding dunes were active prior to, and possibly during, the initial flooding of each basin. Marine records from the Arabian Sea (74KL) show increased Fe values (Fig. 9), implying that aeolian input from the Arabian interior was greater at this time (Sirocko *et al.*, 1993).

The revised chronologies for Awafi and Wahalah reinforce the notion that the shift to humid conditions during the EHHP was not synchronous across the Peninsula. For example, lacustrine deposits date the onset of wetter conditions to ~11.0 k cal a BP at al-Hawa, Ramlat as-Sab'atayn, Yemen, (Lézine *et al.*, 2007), 10.5 ka at Maqta, al-Hajar Mountains, Oman (Fuchs and Buerkert, 2008), and ~9.7 k cal a BP at Mundafan, Rub' al-Khali, Saudi Arabia (Rosenberg *et al.*, 2011). Comparatively later ages are reported from lacustrine deposits at Tayma, An Nafud, Saudi Arabia (~9.2 k cal a BP) (Dinies *et al.*, 2015) and in the Wahiba Sands, Oman (9.3 ka) (Radies *et al.*, 2005). The refined chronologies presented here reveal a modified pattern of lake development at Wahalah from that described in Preston *et al.* (2015), with lacustrine sedimentation commencing ~500 years earlier at ~9.0 k cal a BP. Nonetheless, the new chronologies reaffirm the notion that both sites are out-of-step with many of the palaeoclimate records listed above. The reason for this is unclear, although as outlined in Preston *et al.* (2015), it does not necessarily imply a continuation of aridity in the region. The later onset of lacustrine sedimentation at Awafi (~8.3 k cal a BP) suggests that local factors, possibly related to changing

basin and catchment topography, were more conducive to lake formation at Wahalah during the early Holocene. In this respect it is noted that dune accumulation ceased somewhat later at Awafi (9.1 ka) compared to Wahalah (10.3 ka) (Goudie *et al.*, 2000; Atkinson *et al.*, 2011). We also acknowledge that there is some overlap between the revised ages at the 95% ( $2\sigma$ ) confidence level. At Wahalah, the new age-depth model yields a mean age of 9009 cal a BP (8516 – 9804 cal a BP,  $2\sigma$ ) at 2.06 m. At Awafi, a mean age of 8305 cal a BP (8110 - 8577 cal a BP,  $2\sigma$ ) was derived at 2.50 m. These depths (2.06 and 2.50 m) mark the onset of marl sedimentation at each site. The possibility that lacustrine sedimentation commenced simultaneously at the two sites is thus statistically possible.

Palaeoclimate studies have until recently suggested that the timing of the transition to humid conditions during the EHHP varies according to latitude, reflecting the steady northward shift of the summer ITCZ and associated monsoon rainfall belt into Arabia during the early Holocene (Fleitmann *et al.*, 2007) in response to orbital forcing (Parton *et al.*, 2015). This argument is consistent with the Omani speleothem records, which suggest that monsoon rainfall reached southern Oman (Qunf Cave) by 10.6 ka and northern Oman (Hoti Cave) by 10.1 ka (Fleitmann *et al.*, 2007) (Fig. 9). Despite the absence of speleothem evidence supporting the displacement of the summer ITCZ as far as 27°N (Rosenberg *et al.*, 2013), isotopic analysis of early Holocene groundwater samples from the Liwa and Gachsaran aquifers, UAE (23 to 24°N) suggests a southerly moisture source (Wood, 2010). Indeed, recent palaeoclimate modelling highlights the potential importance of moisture derived from the African monsoon system during interglacial phases (Rosenberg *et al.*, 2013; Jennings *et al.*, 2015). These models estimate an annual precipitation level of between 300 and 600 mm in the study region at 130 ka (Fig 3, Jennings *et*

*al.*, 2015). Furthermore, they suggest that moisture derived from both Indian and African monsoon systems reached the study area during the last interglacial, increasing precipitation between May and December (Jennings *et al.*, 2015). The development of this precipitation regime between ~9.0 and 8.0 k cal a BP, when most palaeoclimate records suggest peak monsoon activity, may have triggered a threshold response in both lake systems. The contribution of MLW rainfall, particularly throughout northern Arabia where such systems are important today, also warrants further investigation (Preston *et al.*, 2015) although the above palaeoclimate models suggest that rainfall from these systems was low in comparison to monsoon-derived sources during the last interglacial (Jennings *et al.*, 2015).

Palaeoclimate records indicate maximum humidity throughout Arabia between 9.0 and 7.0 k cal a BP (Berger *et al.*, 2012), a finding consistent with the evidence discussed here. At Wahalah, Preston *et al.* (2015) suggest the development of permanent lacustrine conditions between ~8.5 and 7.7 k cal a BP (revised chronology; ~9.0 – 7.6 k cal a BP) based on the microfaunal evidence from the site, whereas a peak in scrub woodland taxa (primarily *Acacia* and *Prosopis*) is recorded in the Awafi pollen data at this time (Parker *et al.*, 2004). The evidence presented here suggests that the EHHP (~9.0 and 6.4 k cal a BP) was characterised by overall landscape stability, with the lower flux values suggested to reflect the stabilisation of dunes as conditions became wetter. Leighton *et al.* (2014) demonstrated that dune records from SE Arabia show an abrupt fall in net dune accumulation rates at this time (Fig. 9). During much of the EHHP, the potential for the Rub' al-Khali dune fields to supply sediment would have been limited owing to the wetter conditions, the stabilising vegetation cover (Parker *et al.*, 2004), and the flooding of the Arabian Gulf basin (Lambeck, 1996). Despite this, both records reveal several short-lived

phases of increased detrital sediment flux, the most prominent of which is dated between ~8.3 and 7.9 k cal a BP. At Awafi, Parker *et al.* (2004) reported an increase in the C<sub>4</sub> vegetation component at this time, which was suggested to be a response to increased aridity (Parker *et al.*, 2004). Although this event is recorded in the Wahalah DBD and concentration (ppm) geochemical data reported in Preston *et al.* (2015), it is not as pronounced as it appears in the new data, in particular the new MS flux data. These differences highlight the benefit of MAR and sediment flux data in identifying abrupt, short-term events that otherwise appear muted or are missed in sediment records owing to variable sedimentation rates or dilution effects. Abrupt climatic change around this time has been documented in the African Tropics (Street-Perrott and Perrott, 1990), the Near East (Bar-Matthews *et al.*, 2003), the Arabian Sea (Gupta *et al.*, 2003), and the Thar desert (Dixit *et al.*, 2014a). Corresponding phases of reduced precipitation are also noted in the Omani speleothem  $\delta^{18}\text{O}$  data (Fleitmann *et al.*, 2007) (Fig. 9), supporting the notion that the event led to large amplitude hydrological changes. In SE Arabia we suggest that positive biophysical non-linear feedback led to a prolonged phase of increased aridity, loss of vegetation, increased wind strength or a combination of these factors. Pulses of increased detrital sediment flux are also observed at Wahalah at ~7.6, ~7.2, ~6.8 and ~6.4 k cal a BP, with the earliest event also observed at Awafi. These events were insufficient to initiate large-scale dune accumulation throughout SE Arabia (Leighton *et al.*, 2014) (Fig. 9).

The termination of the EHHP is characterised by considerable temporal heterogeneity, with Arabian palaeoclimate records broadly divided into: (a) those that show a gradual decrease in rainfall from ~8.0 k cal a BP and (b) those that show a more abrupt change at ~6.0 k cal a BP (Rampelbergh *et al.*, 2013). The records from this study fall into the latter category, with aridity

1  
2  
3 369 at both sites more sustained between ~6.4 and 5.0 k cal a BP than at any point during the EHHP.  
4  
5 370 At Awafi a steady increase in detrital sediment flux is recorded from ~6.4 k cal a BP,  
6  
7  
8 371 corresponding with a change to reduced vegetation cover with a greater C<sub>4</sub> component (Parker *et*  
9  
10 372 *al.*, 2004). The increase in OM in the Awafi record between ~6.4 and 5.5 k cal a BP may reflect a  
11  
12 373 shallowing of the water body to more marshy conditions, the input of organic matter derived  
13  
14 374 from the erosion and deflation of early Holocene soil material into the basin or a combination of  
15  
16 375 both. This phase of aridity peaked between ~5.2 and 5.0 k cal a BP. In contrast, at Wahalah a  
17  
18 376 more abrupt change is observed, with peaks in DBD, MS, Al, Fe, K, Si and Ti flux values  
19  
20 377 between ~5.9 and 5.2 k cal a BP. This coincides with a rapid phase of dune accumulation at the  
21  
22 378 site, with 4 m of sand deposited between 5.9 and 5.2 ka (5.9 m ka<sup>-1</sup>) (Atkinson *et al.*, 2011).  
23  
24 379 Leighton *et al.* (2014; p. 11) suggest that the increase in aeolian activity occurred (Fig. 9)  
25  
26 380 following a ‘breached threshold of sediment availability as moisture levels fell’, with increasing  
27  
28 381 sediment availability most likely due to the loss of vegetation. Marine records from the Gulf of  
29  
30 382 Oman show a **small** peak in dolomite at ~5.1 k cal a BP as a consequence of increased  
31  
32 383 terrigenous dust input from the Arabian interior (Cullen *et al.*, 2000) (Fig. 9). The contrasting  
33  
34 384 responses of the Awafi and Wahalah lake records suggest differential sensitivities to increasing  
35  
36 385 aridity, with overall higher precipitation at the former site owing to its closer proximity to the  
37  
38 386 mountain front.  
39  
40  
41 387  
42  
43  
44  
45  
46 388 The termination of the EHHP is widely linked to the steady southward movement of the summer  
47  
48 389 ITCZ from ~8.0 k cal a BP in response to declining solar insolation (Fig. 9), a theory consistent  
49  
50 390 with evidence from the Qunf Cave speleothem record (Fleitmann *et al.*, 2007), as well as  
51  
52 391 sedimentary cores from the Arabian Sea (Sirocko *et al.*, 1993; Gupta *et al.*, 2003), which show a  
53  
54  
55  
56  
57  
58  
59  
60

gradual trend towards dry conditions in the Arabian interior (Fig. 9). Whilst the lake records discussed in this paper show a more abrupt shift as they became disconnected from southerly summer rainfall during the mid-Holocene (Rampelbergh *et al.*, 2013), the sediment archives from both sites reveal long-term changes from ~8.0 k cal a BP. At Wahalah, Preston *et al.* (2015) noted a decline in microfauna (e.g. ostracods and gastropods) at ~7.7 k cal a BP (new chronology; ~7.6 k cal a BP), possibly reflecting a shift from permanent to intermittent conditions at the site. At Awafi, Parker *et al.* (2004) documented a decline in woody vegetation and a small increase in xeric taxa at approximately the same time, broadly corresponding with the abrupt decline in the Na/Ti data from this study. It is thus possible that these changes mark the onset of a progressive decline in precipitation, with rainfall from southern sources reaching the region less frequently after ~8.0 k cal a BP until a threshold was crossed between ~6.4 and 5.9 k cal a BP, triggering a widespread landscape reconfiguration. This view is supported by the abrupt positive shift in the Hoti Cave  $\delta^{18}\text{O}$  speleothem record at 6.3 ka, which is suggested to reflect a change from a southern (monsoon) to a northern (MLW) moisture source (Fleitmann *et al.*, 2007). Despite this, we propose that the termination of the EHHP cannot solely be explained by a simple south – north precipitation gradient. Indeed, the estimated position of the summer ITCZ during the early to mid-Holocene varies between studies (Pietsch and Kühn, 2012), with records from eastern areas of the Peninsula (e.g. Parker *et al.*, 2006; Fleitmann *et al.*, 2007; Fuchs and Buerkert, 2008) generally suggesting a more northerly position later into the Holocene than those in the southwest (e.g. Pietsch and Kühn, 2012). This is further complicated by the potential influence of the African monsoon system, with an associated west – east precipitation gradient across Arabia (Jennings *et al.*, 2015). The importance of orography must also be considered, with records from or close to mountainous regions benefitting from increased

60

precipitation and runoff. Indeed, the orographic effects of the al-Hajar Mountains have already been discussed and are evident in palaeoclimate models (Jennings *et al.*, 2015). A final consideration is the role played by MLW systems at the end of the EHHP. A shift to higher  $\delta^{18}\text{O}$  values in the Soreq Cave speleothem record (Bar-Matthews *et al.*, 2003) and termination of the Hoti Cave record at 5.3 ka (Fleitmann *et al.*, 2007) (Fig. 9) suggests a decline in this source of moisture during the mid-Holocene although the evolution of MLW rainfall (e.g. spatial extension) is not yet precisely defined (Berger *et al.*, 2012).

Following the termination of the EHHP (~6.4 to 5.0 k cal a BP), both records show a reduction in detrital sediment flux between ~5.0 and 4.3 k cal a BP, corresponding with lower net accumulation rates throughout the northeastern UAE (Leighton *et al.*, 2014) (Fig. 9). These changes have previously been suggested to represent a short-term humid phase, the mid-Holocene humid period (MHHP), during which both the Awafi and Wahalah basins contained shallow, intermittent waters (Parker *et al.*, 2006; Preston *et al.*, 2015). An increase in the  $\text{C}_4$  vegetation (Parker *et al.*, 2004) suggests that the prevailing climate between ~5.0 and 4.3 k cal a BP was drier than between ~9.0 and 6.4 k cal a BP. Based on the current palaeoclimate evidence, it remains unclear whether this was a regional or more localised phase. Indeed, aside from the lake records presented here, very few archives show humid conditions at this time and those that do are predominately located in the southwest of the Peninsula (e.g. soil development in the Dhamar Highlands) where rainfall remains higher today (Davies *et al.*, 2006). Since no palaeomonsoon records show a re-advance of the ITCZ at this time, we propose these humid conditions were primarily driven by increased MLW precipitation. An increase in MLW precipitation at this time is not consistent with the hiatus in the Hoti Cave speleothem record

438 between 5.3 and 2.6 ka (Fleitmann *et al.*, 2007) although a brief humid phase is recorded in the  
 439 Soreq Cave speleothem record between 4.8 and 4.7 ka (Bar-Matthews and Ayalon, 2011).  
 440 Determining the spatial extent of the MHHP is challenging owing to possible removal of  
 441 sediments by erosional processes during the predominately arid conditions that have prevailed  
 442 since the mid-Holocene, with evidence only preserved at sites protected from the effects of such  
 443 processes (e.g. archives at higher elevations, in areas of high groundwater, etc.). The deposition  
 444 of aeolian sand in the Awafi lake basin at 4.10 ka marks the total desiccation of the water body.  
 445 A corresponding increase in detrital sediment flux is recorded at Wahalah, with a peak in activity  
 446 dated between ~4.2 and 3.9 k cal a BP. At Al Ain, UAE, 7 m of dune accumulation occurred  
 447 between 4.4 and 4.1 ka giving a net accumulation rate of 26 m ka<sup>-1</sup> (Atkinson *et al.*, 2011). This  
 448 event has a global signature and is identified in palaeoclimate records throughout Arabia (Arz *et*  
 449 *al.*, 2006; Berger *et al.*, 2012), as well as other areas influenced by the monsoon system (Street-  
 450 Perrott and Perrott, 1990; Cullen *et al.*, 2000; Staubwasser *et al.*, 2003; Tierney and deMenocal,  
 451 2013; Dixit *et al.*, 2014b) (Fig. 9).

452  
 453 Previous studies have highlighted a potential link between abrupt events identified in the Awafi  
 454 and Wahalah sediment records and Bond Events (Bond *et al.*, 1997) driven by reduced sea  
 455 surface temperatures (SST) in the North Atlantic (Parker *et al.*, 2006; Preston *et al.*, 2015).  
 456 Indeed, the abrupt increases in detrital sediment flux identified in this study between ~8.3 and  
 457 7.9 k cal a BP, at 5.9 k cal a BP, and between ~4.3 and 3.9 k cal a BP fall within periods of rapid  
 458 climate change identified by Mayewski *et al.* (2004), which were typically characterised by  
 459 reduced temperatures at high latitudes, increased aridity throughout the lower latitudes, and  
 460 major changes to atmospheric circulation, including reduced monsoon intensity. We propose that

in SE Arabia these events drove threshold changes across the landscape, with resultant fluctuations in lake levels, sediment availability and flux rates.

**Conclusions**

Sediment flux data from SE Arabia show the sensitivity of high-resolution terrestrial records from this region. The revised chronologies presented in this paper reaffirm the notion that the Awafi and Wahalah records are out-of-step with other palaeoclimate records from Arabia. This may partly reflect the gradual northwards migration of the summer ITCZ and associated Indian monsoon rains during the EHHP (~9.0 to 6.4 k cal a BP) although the contribution of moisture derived from the African monsoon system as well as MLW at this time remains uncertain and warrants further investigation. Despite maximum lake expansion, vegetation cover, and overall landscape stability during the EHHP, several pulses of increased detrital sediment input are recorded at the study sites, the most prominent dates between ~8.3 and 7.9 k cal a BP, and are suggested to reflect short-lived phases of increased aridity. The termination of the EHHP is linked to southwards migration of the summer ITCZ to its present position from ~8.0 k cal a BP. The abrupt changes observed at both sites between ~6.4 and 5.9 k cal a BP may reflect a threshold response of the landscape to this long-term decrease in precipitation, with aridity peaking between ~5.2 and 5.0 k cal a BP. This was followed by a period of reduced detrital sediment flux during the MHHP (~5.0 to 4.3 k cal a BP), which is suggested to reflect a brief return to more humid conditions. The spatial extent of the proposed increase in moisture remains unclear. The termination of the MHHP is marked by an abrupt increase in detrital sediment flux in both records between ~4.3 to 3.9 k cal a BP. This event, as well as the suggested increases in aridity between ~8.3 and 7.9 and at ~5.9 k cal a BP, is coeval with phases of rapid global climate

change, which appear to have driven non-linear changes throughout the SE Arabian landscape characterised by dune reactivation, lake lowering and vegetation loss.

## ACKNOWLEDGEMENTS

The underlying concepts for this research were heavily influenced by the work of Alayne Street-Perrott and the seeds sown whilst AGP was a research student under her supervision. We thank Christian Velde and Imke Moellering, Department of Antiquities, Government of Ras' al-Khaimah, for permission to work in the area and for providing logistical support. PEJ is funded by NERC grant NE/KOO5294/1. Finally, the authors wish to thank the two anonymous reviewers and the guest editor for their constructive feedback on earlier drafts of this manuscript.

802

803 Figure 5: Age-depth plots for (a) Wahalah and (b) Awafi. Blue symbols (on-line version) show

804 the  $^{14}\text{C}$  and OSL dates and their associated uncertainties. Solid lines are the mean MCMC-

805 derived age-depth models and the dashed lines are the 95% confidence intervals.

806

807 Figure 6: Sedimentation rates for (a) Wahalah and (b) Awafi with ages derived from the mean

808 age-depth model for each site (refer to Fig. 5). Solid lines are the mean MCMC-derived

809 sedimentation rates and dashed lines are the 95% confidence intervals.

810

811 Figure 7: Sediment flux records for Awafi showing the key palaeoclimatic periods. The darker

812 grey bands indicate periods of increased sediment flux and climatic aridity as discussed in the

813 text.

814

815 Figure 8: Sediment flux records for Wahalah showing the key palaeoclimatic periods. The darker

816 grey bands indicate periods of increased sediment flux and climatic aridity as discussed in the

817 text.

818

819 Figure 9: Comparison of palaeoclimate records from Arabia and surrounding regions (refer to

820 Fig. 1 for the location of each site): (1) Insolation at  $30^\circ\text{N}$  (Berger and Loutre, 1991), (2) Dune

821 net accumulation rates from SE Arabia (Leighton *et al.*, 2014), (3) Wahalah MS signal ( $10^{-5} \text{ cm}$

822  $\text{a}^{-1}$ ), (4) Wahalah Ti flux record ( $\text{mg cm}^{-2}\text{a}^{-1}$ ), (5) Awafi MS signal ( $10^{-5} \text{ cm a}^{-1}$ ), (6) Awafi Ti

823 flux record ( $\text{mg cm}^{-2}\text{a}^{-1}$ ), (7)  $\delta^{18}\text{O}$  Soreq Cave speleothem record (Bar-Matthews *et al.*, 2003), (8)

824  $\delta^{18}\text{O}$  Hoti Cave speleothem record (‰) (Neff *et al.*, 2001), (9)  $\delta^{18}\text{O}$  Qunf Cave speleothem
